ABSTRACT
The effectiveness of the OMNI-RES (0-10) and the electromyographic signal for monitoring changes in the movement velocity was examined during a set to muscular failure using different percentages of one repetition maximum (1RM) in the parallel squat exercise (PSQ). Twelve males (26.3 ± 5.8 years) were evaluated on eight separate days with 48 hours of rest between sessions. After determining the 1RM value, participants underwent seven tests until achieving muscular failure with the following percentage ranges: 30 to <40%; 40 to <50%, 50 to <60%, 60% to <70%, 70 to <80%, 80 to <90% and >90%. An optical rotary encoder measured mean accelerative velocity (MAV) and the OMNI-RES (0-10) scale was used to express the Rating of Perceived Exertion (RPE) after every repetition of each set. Additionally, the normalized root mean square (RMS) signal of the surface electromyography (N-EMG) was calculated for the vastus medialis muscle. The RPE expressed after the first repetition and when the maximum value of MAV was achieved along the sets was lower (p <0.001, d >0.8) than the RPE that corresponded to a 10% drop in MAV and at failure. Additionally, the initial RPE was useful to distinguish different loading zones by anchoring the OMNI-RES value to the magnitude of the relative load (<60%, 60 to <70% or ≤ 70% 1RM). Similar patterns were observed using the N-EMG. In conclusion, apart from differentiating between relative loads during a set to failure in the PSQ, the RPE and the N-EMG can both reflect changes associated with the initial, maximal, 10% drop in movement velocity and the muscular failure.

Key words: RPE, OMNI-RES (0-10) scale, accelerative velocity, muscular failure, EMG, neuromuscular activity
INTRODUCTION

The use of different rating of perceived exertion (RPE) scales to monitor the progression of fatigue and changes in velocity during resistance exercises has been analysed in several investigations (6, 12, 27, 29). A limited number of studies have examined the relationship between the mechanical (15) or muscular activation (9, 17, 25) responses and the RPE. Even though the level of muscular activation seems not to be related to changes in the RPE when training with constant loads (17), some studies reported significant correlations between the intensity and the level of elicited muscular activity expressed after performing upper (25) and lower body (9) resistance exercises. Increases in muscular activity are a direct result of motor efferent commands, which, in turn, cause an increase in the number of corollary signals toward the sensory cortex that may regulate the perception of exertion (24). The aforementioned neurological and perceptual effects would be determined by an increase in exercise intensity (25) and/or the number of repetitions performed per set or over a whole training session (29). Furthermore, the ability of perception to reflect the level of fatigue in terms of power output (15) or movement velocity (27) using different percentages of the maximal weight that can be lifted in one maximal repetition (1RM) have been previously demonstrated. The aforementioned studies support the use of perception scales to monitor the variation of the velocity in order to stop the set before a decline in velocity below a desirable level occurs as a consequence of fatigue. Two of the most important variables affecting the performance outcomes of resistance training are the relative load (% 1RM) and the movement velocity (28). Even though light (<60%), moderate (>60 to 80%) and heavy (>80%) loads have been traditionally associated with endurance, hypertrophy, and maximal strength training outcomes respectively (1), when training for power, the resistance must be moved at the highest possible velocity (29). A decrease greater than 10% of the maximal velocity, for a given relative load, has been associated with a change from power toward more endurance-oriented strength (32). This drop in the mechanical
performance would be attributable to a selective fatigue of fast motor units along with a progressive activation of the slow motor unit (8). Additionally some linear models have successfully correlated changes in EMG signal and power loss to assess acute changes in the capability to apply force during resistance exercises (20, 21). To the best of the authors’ knowledge the sensitivity of both the perceived exertion and the electromyographic signal to differentiate specific moments within the set where the movement velocity peaks, drops below 10% from the maximum, or where the set approaches muscular failure still need to be properly investigated.

Consequently the aim of this current study was to explore the perception of effort and neuromuscular activity where the movement velocity peaks, decreases 10% with respect to the maximum, and at muscular failure during a continuous set, using different percentages of the 1RM in the free weight parallel squat (PSQ) exercise. Furthermore, the ability of the RPE and the neuromuscular activity to discriminate between relative loads across a wide range, from 30 to 100%, divided into 10% incremental slots was also investigated. To reach these objectives the following hypotheses were formulated: 1) the RPE and the electromyographic signal at the end of the repetition will show significant differences between specific moments within the set where the velocity concomitantly reduced as the set approaches muscular failure; and 2) the RPE and the electromyographic signal measured at the beginning of each set will differentiate relative loads (as a percentage of 1RM) utilized.

METHODS

Experimental Approach to the Problem

This study was designed to examine the applicability of the RPE and the electromyographic signal as methods for discriminating the relative load and reflecting changes in the movement velocity during a continuous repetition set until muscular failure using different percentages of
1RM in PSQ. After determining the individuals’ 1RM values, participants were evaluated on seven occasions until achieving muscular failure with the following 1RM percentage ranges: 30 to <40%; 40 to <50%, 50 to <60%, 60% to <70%, 70 to <80%, 80 to <90% and >90%. The mean accelerative velocity (MAV), the OMNI-RES (0-10) scale value, as a measure of the RPE, and the root mean square (RMS) surface electromyography signal (amplitude EMG) were obtained for all the repetitions of each set. The study assessed whether the instances where the movement velocity peaks, drops 10% from the maximum, or reaches muscular failure show different values of the subjective perception of effort and the neuromuscular activation measured over a set using seven percentage ranges (30 to 100% of 1RM) in PSQ.

**Subjects**

Twelve recreationally resistance-trained males (age 26.3 ± 5.8 years, body mass 81.1 ± 13.6 kg and height 178.1±4.5 cm), with a minimum of two years of experience performing squatting exercises volunteered to take part in this study. Prior to participation, all participants read and signed an informed consent previously approved by the University’s Ethics Committee.

**Procedures**

Before the beginning of the study all the participants underwent two familiarisation sessions. During these sessions, standard instructions, and RPE OMNI-RES (0-10) scale anchored procedures were explained to the participants in order to properly reflect the RPE for the whole body (31) after performing each singular repetition of the different resistance exercises including the PSQ.

The OMNI Perceived Exertion Scale for Resistance Exercise (OMNI-RES) developed and validated by Robertson and colleagues (31), includes both verbal and mode-specific pictorial descriptors distributed along a comparatively narrow response range of 0 to 10 (Figure 1). These
characteristics make the OMNI-RES scale a useful methodology to control the intensity of resistance exercises over other previously published scales.

Exercise:
The PSQ was performed using free weights and a squat rack. Participants were instructed to start the exercise from standing, feet parallel and shoulder width apart with toes pointing slightly outward. The bar was either centred across the shoulders just below the spinous process of the C7 vertebra (high-bar position) (33). Participants were instructed to squat down with a controlled velocity until their posterior thigh was positioned parallel to the floor. After a minimum pause (less than 1 s), participants performed the concentric squatting phase with the maximal possible velocity. One qualified instructor (a certified strength and conditioning coach, CSCS or UK Strength and Conditioning Association) monitored the appropriate range of motion.

Evaluation sessions:
The 1RM PSQ was determined in the first session. After 48 h rest and based on the 1RM results, participants performed seven-assessment sessions separated by 48 hours of rest. Each session comprised only one repetition to failure (RTF) test using the following 1RM percentages: 30%; 40%; 50%; 60%; 70%; 80% and 90%. As the availability of the free weight equipment (20 kg Olympic bar, 1.25, 2.5, 5, 10, 15 and 20kg discs) did not always permit obtaining the exact amount of kg representing the aforementioned percentages, the nearest amount of kg provided it being equal or up to a maximum of 10% greater than the reference was considered for the test. Therefore the following seven percentage evaluation ranges were determined: 30 to <40%, 40 to <50%, 50% to <60%, 60 to <70%, 70 to <80%, 80 to <90% and >90%. In order to minimize the accumulated fatigue effect, sequencing of the RTF tests was randomized. Furthermore, participants were asked to abstain from any unaccustomed or hard exercise and refrain from
caffeine intake, whilst maintaining similar sleeping hours and daily activities during the testing period.

**Measurement of velocity:** An optical rotary encoder (Winlaborat®, Buenos Aires, Argentina, model WLEN01) with a minimum lower position register of 1 mm connected to the proprietary software Real Speed Version 4.20 was used for measuring the position and calculating the velocity \( (v) \) in \( \text{m} \cdot \text{s}^{-1} \) achieved during each repetition of the PSQ. The cable of the encoder was connected to the bar in such a way that the exercise could be performed freely; which enabled the cable to move in either vertical direction of the movement. In order to avoid underestimation of the neuromuscular performance, the mean accelerative velocity (MAV) calculated from the accelerative portion of the concentric phase, during which the acceleration of the barbell was \( \geq -9.81 \text{ m} \cdot \text{s}^{-2} \) was used for estimating changes in movement velocity (13).

The analysis of the MAV achieved during the RTF test was based on four specific events determined at: 1) the first repetition (MAV-1); 2) the repetition where the maximum value of MAV was achieved along the corresponding set (MAV-max); 3) the repetition where a drop of 10% in the MAV with respect to the MAV-max was identified (MAV-10%); and 4) the MAV measured during the last repetition (MAV-F), just before the muscular failure on the last repetition of each set. A 10% drop in the MAV was selected because a decline of such magnitude when performing explosive resistance exercises has been associated with selective fast twitch fibres’ fatigue and a loss of movement speed which is not recommended for power development in athletes (19). The criterion analysis to determine the time point associated with the MAV-10% was the performance of two continuous repetitions with a 10% reduction from the MAV-max.
**Control of the rating of perceived exertion (RPE):**

During the familiarisation sessions and the RFT tests the participants were instructed to verbally report the RPE value indicating a number of the OMNI-RES (0–10) scale that reflects their overall muscular effort at the end of each repetition of the PSQ. The investigators used the same question before starting the first set of each exercise during the familiarization sessions and immediately prior to each of the seven RTF tests: “how hard do you feel your muscles are working during the exercise?” (30). A rating of 0 was associated with no effort (seating or resting), and a rating of 1 corresponded to the perception of effort while performing an extremely easy effort (26). A rating of 10 was considered to be maximal effort and associated with the most stressful exercise ever performed (23). The OMNI–RES (0-10) scale was in full view of participants at all times during the procedures.

**Electromyography data collection:**

The dominant limb was selected for data collection. Prior to electrode placement, the skin was shaved, abraded and cleaned with isopropyl alcohol. Differential bipolar (10 mm centre to centre) surface electrodes (DE-2.1, DELSYS, USA) were then placed over the vastus medialis of the quadriceps muscle in accordance to SENIAM guidelines (16). A single reference electrode was placed on the C7 vertebra and all leads connected to the electrodes were secured with tape to avoid artifacts from limb movements. EMG signals were amplified (1 k gain) via a Delsys Myomonitor system with EMGworks software 3.1 (Delsys Inc. Boston, MA, USA) with a bandwidth of 20–450 Hz. RMS analysis was performed on each repetition using Python programming language version 3.4.1. (Python Software Foundation). Data were collected throughout the entire RTF test for all the seven evaluated ranges. As the vertical displacement during the concentric phase (ascending movement) was recorded by the rotary encoder and time-synchronised with the EMG signal, only the EMG data relating to the concentric phase of each
repetition was analysed. As the present study was focused on identifying changes in the accelerative velocity at four specific moments along each continuous set, the RMS signal was considered as the primary data for the analysis. The RMS value is the standard method for defining the effective amplitude of a time-varying, alternating signal, providing a meaningful representation of muscle activation at each of the analyzed time points (18).

Maximum Voluntary Isometric Contraction (MVIC) test:
For normalization purposes, each participant completed a 5 seconds MVIC maintaining a squat position keeping the trunk erect and the knee joint angle at 90° (anatomical angle). The exercise was performed on a rack that was secured in order to avoid any movement of the resistance. This knee joint angle was selected based on previous observations, which demonstrated that peak acceleration force occurred near this point in the range of motion immediately after overcoming the sticking region during the concentric movement in squat (10). The muscle activity of the vastus medialis was recorded and considered the reference value for normalizing the RMS signal (N-EMG) measured during the RTF tests. In order to avoid potential sources of error by moving or reapplying electrodes, the MVIC was performed at the beginning of every RTF test after the electrodes were applied.

The reliability of the RTF test used in this study has been demonstrated in previous pilot and published studies (29) of our research group that found test-retest intraclass correlation coefficients (ICC) to be >0.92 for both the MAV and the RPE values obtained from the OMNI-RES (0-10) scale

Dependent Variables
Three main dependent variables (MAV, RPE and N-EMG) were analysed for each of the RTF tests. Furthermore, in order to assess the electromyographic signal and the perceived exertion to
reflect changes in mechanical performance over a set to failure, the previously identified four consecutive time points for the MAV (MAV-1, MAV-max, MAV-10% and MAV-F) were also used to determine the corresponding values of RPE and N-EMG. Table 1 depicts the main three variables and the four different points identified for each of the seven RTF tests.

Table 1

Statistical Analysis

Means and standard deviations (SD) were determined for all of the variables analysed during the 1RM and RTF tests. Mauchly’s Test of Sphericity was used for testing the normality of the difference data between all possible pairs of within-subject conditions. For each seven tested percentage range data, one way repeated measures analysis of variance (ANOVA) was applied to detect differences between the four time points identified for each dependent variable (MAV, RPE, and N-EMG). Repeated measures ANOVAs were also performed to determine differences between percentage ranges among each time point data for each variable. Bonferroni-adjusted post-hoc analyses were performed as appropriate for pairwise comparisons. Generalized eta squared (η²G) and Cohen’s d values were reported to provide an estimate of standardized effect size (small d=0.2, η²G=0.01; moderate d=0.5, η²G=0.06; and large d=0.8, η²G=0.14). In order to provide useful information for controlling the load estimate, changes in movement velocity through the perception of effort the CIs (95%) of the RPE variables were calculated. Average values are reported as mean±SD unless stated otherwise. Statistical power for the evaluations ranged from 0.85-1.00. The significance level was set at 0.05.

RESULTS

The 1RM mean value was 128.3±26.3 kg (1.6±0.3 kg·body weight⁻¹). The average relative load values and the total number of repetitions performed in each of the seven ranges were as follows: 1) 31.04±0.71% and 50.9±10.7 repetitions; 2) 41.04±0.90% and 34.3.1±4.7 repetitions; 3)
50.9±0.27% and 30.7±5.3; repetitions; 4) 60.68±0.57% and 19.6±2 repetitions; 5) 71.98±0.51% and 14.7±2.5 repetitions; 6) 80.92±0.61% and 9.2±1.4 repetitions; 7) 91.03±0.85% and 4.8±1.0 for 30 to <40%, 40 to <50%, 50% to <60%, 60 to <70%, 70 to <80%, 80 to <90% and >90% respectively.

Table 2 shows the mean±SD for the three main variables (MAV, RPE and N-EMG) and the corresponding four time points analysed along the RTF test within and across the seven ranges evaluated.

Table 2

Mean Accelerative Velocity (MAV):

Comparison of the four time points within each range: Significant main time effects were observed for the seven ranges. Pairwise comparison revealed that with the exception of three lowest ranges (30 to <40%; 40 to <50% and 50 to <60%) where MAV-1 was similar to MAV-10% and the heavy ranges (70 to <80%; 80 to <90% and >90%) where MAV-1 was similar to MAV-max, significant differences (p <0.001) and large effect sizes (d >0.80) were determined for all the performed pairwise comparisons (Table 2).

Comparison of each of the time points across the ranges: Significant main range effects were observed for the four analysed time points. Pairwise comparison revealed that the MAV-1 was different (p <0.001 d >0.8) when comparing lower (30 to <60%) moderate (60 to <70%) and heavy (80 to <90% and >90%) percentages ranges. Additionally the MAV-max was different (p <0.001 d >0.8) between all the percentages with the exception of the two lowest ranges. The MAV-F at 30-40% range was significantly higher (p <0.05, d >1) than the MAV-F achieved at moderate to heavy ranges (60 to <90%). Additionally the MAV-F at 50 to <60% was higher than the MAV-F measured at ≤80- (p =0.034, d =1.20). No differences were observed between the MAV-10%.
Rate of Perceived Exertion (RPE):

Comparison of the four time points within each range: Significant main time effects were observed for the seven ranges. Bonferroni post hoc revealed that the RPE values expressed at RPE-1 and RPE-max were similar and significantly lower (p <0.001, d >0.8) than the RPE-10% and RPE-F for all the evaluated ranges (Table 2).

Comparison of each of the time points across the ranges: Significant main range effects were observed for the RPE-1; RPE-max and RPE-10%. Pairwise comparison revealed that The RPE-1 and RPE-max were significantly different (p <0.001; d >0.8) between lower (30 to <60%) moderate (60 to <70%) heavy (80 to <90%) and maximal (>90%) percentages ranges (Table 2). No differences were observed between the RPE-10% and RPE-F across the seven range percentages.

Table 3 shows the 95% CI limits for the four analysed RPE variables. The presented data expresses the potential range of RPE values that could be used for selecting the load and estimate changes in movement velocity while performing continuous sets to failure from light to maximal loads (30 to >90% 1RM) in the PSQ exercise.

Table 3

Amplitude EMG, Normalized root mean square signal (N-EMG):

Comparison of the four time points within each range: Significant main time effects were observed at 40 to <50%; 50 to <60%; 60 to <70%; 80 to <90% and >90% ranges. No other main time effects were determined. Bonferroni post hoc revealed significant lower N-EMG-F values compared to N-EMG-max at >40%-50% (p =0.002, d =1.18) and to N-EMG-1 (p =0.013, d =0.85) at 50-60%. Furthermore, strong trends were observed between N-EMG-F and N-EMG-max at 50% to <60% (p =0.08, d =0.54) and 60 to <70% (p =0.069, d =0.58) as well as from N-
EMG-F to N-EMG-1 (p =0.063, d =0.60) at 60 to <70%. The N-EMG-1 showed significant higher values (p <0.05, d >0.5) at 80 to <90 and >90% with respect to the other three assessed time points. No other differences were observed (Table 2). 

Comparison of each of the time points across the ranges: Significant main range effects were observed for the N-EMG-max and N-EMG-10%. Pairwise comparison revealed that the N-EMG-max was significantly lower at 30 to <40% compared to the other 6 ranges (p <0.001, d >0.80). Additionally, higher N-EMG-max was determined for both 40 to <50% and 50 to <60% compared to the heaviest ranges (p <0.01, d >1) (80 to <90 and >90%). The N-EMG-10% was significantly lower at 30 to <40% compared to the others percentage ranges (p <0.01, d >0.80) but not with respect to >90%. In addition the N-EMG-10% measured at >90% was lower than the values obtained at 40% to <50; 50% to <60% and 70 to <80% (p <0.05, d >0.5). No other main range effects were observed.

DISCUSSION

The main finding of the present investigation was that the RPE measured by the OMNI-RES (0-10) scale is a valuable methodology to detect movement velocity fluctuations during a continuous set until volitional failure and to discriminate the relative load used (% 1RM) in the PSQ. The proposed approach utilizes the perception of effort at the beginning (RPE-1), and at different times over a continuous set to monitor mechanical events associated with different strength manifestations (explosive, endurance or maximal) and the corresponding outcomes. The RPE-1 and RPE max were similar for all the evaluated ranges but different from RPE-10% and the RPE-F. Thus, controlling the RPE from the beginning and along a set performed with the maximal possible movement velocity would be a suitable method to estimate the moment where a drop of about 10% occurs, and to monitor the progression toward the muscular failure.
Overall, the MAV was different at the four evaluated time points for each individual 10% slot. Interestingly, at the lightest three ranges (30% to <60%), the MAV-1 was similar to MAV-10% and lower than MAV-max. Reaching a maximum movement velocity using light loads may require 2 or 3 previous repetitions to elicit the maximal muscular activation for achieving the highest possible velocity during the ascending phase (4, 5). Thus, although further analysis would be necessary for explaining the reason for such as responses, the lower values of MAV-1 may be related to the lack of specific previous neuromuscular preparation. Meanwhile the drop of 10% in the MAV could be associated with a selective fast motor unit disconnection observed during continuous repetitions performed with the maximal possible velocity (32).

Even though the N-EMG signal analysed in the present study was unable to accurately reflect small (~10%) fluctuations of the movement velocity, the overall lower values measured at N-EMG-10% and N-EMG-F for almost all percentage ranges (≥40%) would be in some way associated with the progression of the set after overcoming the repetition anchored to the RPE-10%. The progressive decrease of the N-EMG signal observed in the present study is different from the incremental pattern response reported by Hollander et al (18) who suggested a rise of the normalised RMS signal as the contraction duration increases between 2, 3, 4 and 5 sec in the knee extension exercise. Differences in the performed exercises, including mechanics (closed vs. open kinetic chain), the amount of muscle mass (multi-joint vs. single joint exercise) and the mode of execution (explosive vs. controlled) would have influenced the present results.

Participants of the present investigation performed the PSQ exercise with the intention to reach the maximal velocity at the end of concentric phase from the first repetition of each RTF test meanwhile in the Hollander et al. study, the participants were instructed to complete the knee extension exercise over a 90° range of motion at predetermined four contraction durations (2s, 3s, 4s and 5s). In the present study, the available limited time to achieve the full contraction when performing exercises with the maximal possible velocity with light loads would allow the
activation of mainly the fast motor units (32) which in turn fatigue at a faster rate (2), disconnecting and influencing the observed descending pattern of the N-EMG signal as the set progresses toward muscular failure.

In summary, the analysis within each range permits the acceptance of the first hypothesis supporting the ability of the RPE and in some way the N-EMG to show changes in the movement velocity during continuous repetitions sets in the PSQ.

The analysis across the ranges indicates that either the RPE-1 or the RPE-max are similar when comparing assessments across the first three ranges (>30%-60% of 1RM). However, the RPE-1 would be a good indicator for differentiating loads associated with light (≤60% 1RM), moderate (60 to <70% 1RM) and heavy (≥70% 1RM) relative loads. Although N-EMG-1 showed no difference between ranges, N-EMG-max displayed a similar pattern as observed for the RPE with higher values measured at 40 to <60% 1RM compared to the values observed at the highest load (≥80% 1RM). Even though the amplitude of EMG signals has been associated with the number of active motor units and their discharge rates, the shape and propagation velocity of the intracellular action potentials, which is also sensitive to the placement of the electrodes, could be even more influential (2, 7) and, therefore it could be possible that when exercises are performed near or at the maximal levels of voluntary contraction the amplitude decreases (14, 22).

The lower levels of N-EMG-max determined for the lightest range (30 to <40%) could be explained by the inability of the participants to produce a maximal neural input when trying to perform explosive movement using very low resistances (<40% 1RM). This capability entails a specific physical conditioning requiring specifically oriented training interventions (3). The present results permit the acceptance of the second hypothesis of utilizing the RPE and the neuromuscular signal to differentiate between light, moderate and heavy loads or 1RM percentages, but not for making a more selective discrimination in 10% incremental loads as used for the present study.
Similar to the present study, Hollander et al (18) also reported that relative loads can be clearly delineated by perceived exertion at least in 20% increments (30, 50 and 70%). However, different from the present investigation where participants performed a multi-joint exercise (squat) with the maximal possible velocity during the ascending phase, Hollander et al. used a single joint exercise (leg extension) controlling the duration of both concentric and eccentric phases (2, 3, 4 and 5 sec). It could be possible that if in the present study a more controlled slow pattern of contraction had been used, a clearer differentiation of perception of the gradation of the submaximal loads along with a progressive increase in the muscle activation as the load approaches the maximum could have been observed. It is important to note that the current study analysed young, recreationally resistance-trained men performing the PSQ and familiarised with the use of OMNI-RES (0-10) scale. Therefore, the present results cannot be applied to other populations such as high performance athletes or other exercises and modalities, especially if there are significant mechanical differences (i.e. a single joint exercise like arm curl, or cyclic total body exercises like running) or employ different muscle groups (i.e. upper body like bench press), which have been shown to produce different effort perceptions at the same percentage and repetitions when compared to lower body exercises (11). Although similar perceptual responses and neurophysiological performance would be observed in women or elderly trained participants, further study is required. Moreover, a limited number of participants (n=12) were studied. The strength of the data, however, was that participants served as their own controls, reducing the variability, and the design involved randomization for assigning different load conditions. In conclusion, results from the present study corroborate the functional linkage among three main effort markers: performance (MAV), perceptual (RPE) and neuromuscular (EMG response), during resistance exercises, and support the use of the RPE estimated from the OMNI-RES (0-10) scale to both estimate the relative amount of the load and to control the training zone approached during the strength oriented workouts.
PRACTICAL APPLICATION

From the practical point of view, the main contribution of the present investigation was to show the ability of the RPE to estimate mechanical events occurring at different instances along a set performed to muscular failure with different percentages of the 1RM load. Despite generalizability issues, this approach can help coaches and athletes to distinguish different resistance training zones by anchoring the RPE-1 to the magnitude of the relative load (% 1RM) and the RPE-max and RPE-10% to the moments along the set where the MAV-max and MAV-10% are respectively produced. For instance, to improve explosiveness with light (30 to <50%), moderate (50 to <70) or heavy (70 to <80%) loads, the initial RPE would be around 1-2; >2-3 or 4-5 for the 30 to <50%; 50 to <70% or 70 to <80% relative loads and never reach values greater than 7 or 8 for the 30 to <50% and 50 to <80% 1RM ranges respectively. Furthermore, for strength-oriented training where the relative load should be over 80% of 1RM (1) the recommended RPE-1 would be between 6 and 7, increasing suddenly to over 8 when the MAV drops 10% and approaches the value of 10 at failure.

One way ANOVA

- MAV: p<0.001, N=60, 50% and >50% to the others.
- MAV-max: p<0.001, N=60, 50% and >50% to the others.
- MAV-10%: p<0.001, N=60, 50% and >50% to the others.
- MAV-F: p<0.001, N=60, 50% and >50% to the others.

RPE (0-10) scale; N=60, 50% and >50% to the others.

One way ANOVA

- RPE-1: p=0.005, N=60, 50% and >50% to the others.
- RPE-max: p=0.005, N=60, 50% and >50% to the others.
- RPE-10%: p=0.005, N=60, 50% and >50% to the others.
- RPE-F: p=0.005, N=60, 50% and >50% to the others.

N-EMG (%)

One way ANOVA

- N-EMG-1: p<0.001, N=60, 50% and >50% to the others.
- N-EMG-max: p<0.001, N=60, 50% and >50% to the others.
- N-EMG-10%: p<0.001, N=60, 50% and >50% to the others.
- N-EMG-F: p<0.001, N=60, 50% and >50% to the others.

Oneway ANOVA

- N-EMG: p<0.001, N=60, 50% and >50% to the others.

**MAV** = mean accelerative velocity; **RPE** = rate of perceived exertion from OMNI-RES (0-10) scale; **N-EMG** = normalized room mean square signal

**Differences within each range: MAV**: a p<0.001 between the four assess time points with the exception of MAV-1 vs MAV-10%. b p<0.001 between the four assess time points; c p<0.001 between the four assess time points with the exception of MAV-1 vs MAV-max. **RPE**: d p<0.001 from RPE-1 and RPE-max to RPE-10% and RPE-F. **N-EMG**: e p<0.005 from N-EMG-max to N-EMG-F; f p<0.005 from N-EMG-1 to N-EMG-10% and N-EMG-F to the others three time points;**

**Differences across ranges: MAV**: a p<0.001 from the >30-40 vs >40-50% and >50-60% to the other ranges; b p<0.005 from >60-70% to the other ranges; c p<0.05 from 30-40% to >60-70%, >70-80% and >80-90%; d p=0.034 from 50-60% to >80-90%. **RPE**; e p<0.001 from the >30-40 vs >40-50% and >50-60% to the other ranges f p=0.001 >60-70% to the others ranges. **N-EMG**: g p<0.001 respect to the other ranges; h p<0.05 to 40-50% to 50%-60% and >70-80%.
Table 3. Mean CI (95%) determined on the RPE main variables determined along the seven-repetition to failure test.

RPE-1 indicates OMNI-RES scale value determined after doing the first repetition of each repetition to failure test. RPE-max indicates OMNI-RES scale value of the repetition where the maximal mean accelerative velocity was reached in each repetition to failure test. RPE-10% indicates OMNI-RES scale value expressed when a 10% decrease in the mean accelerative velocity was determined along each repetition to failure test. RPE-F indicates the OMNI-RES scale value expressed after performing the last repetition of each repetition to failure test.
