Introduction: Resin-based fissure sealants (RBFS) are placed over the occlusal surfaces of premolars and molars to prevent cariogenic microorganisms and organic debris from accumulating in the pits and fissures[1]. UltraSeal XT® hydro™ (Ultradent Products, USA) is a new hydrophilic acrylate-based sealant which is filled with a mixture of inorganic particles.

The application of Er:YAG laser irradiation to precondition teeth prior to the placement of RBFS is reported to improve adhesion and microleakage-resistance; however, the efficacy of laser-conditioning appears to depend upon the laser settings and physicochemical properties of the sealant[1],[2]. The purpose of this study was to investigate the microleakage and enamel-sealant interface of UltraSeal XT® hydro™ as a function of different enamel etching techniques.

Materials and Methods: Occlusal surfaces of sound extracted human molars were either conventionally acid-etched, Er:YAG laser-irradiated, or successively acid-etched and laser-irradiated. The 2940 nm Er:YAG laser (LightWalker®, Fotona, Slovenia) was applied with an energy density of 19 mJ cm⁻², power output of 1.2 W, and pulse energy of 120 mJ. UltraSeal XT® hydro™ was applied to each group of teeth (n = 10) which were then subjected to 2500 thermocycles between 5 and 55 °C with a dwell-time of 30 s. Microleakage assessments were carried out using optical and scanning electron microscopies. Microleakage score data were analysed using the Kruskal-Wallis, Mann-Whitney U test.

Results and Discussion: No significant differences in microleakage were noted between the individually acid-etched and laser-irradiated groups (p > 0.05); however, teeth treated with a combination of acid-etching and laser-irradiation demonstrated significantly lower microleakage (p < 0.001).

Electron microscopy revealed that laser-ablation increases the surface roughness of the enamel and causes regions of sub-surface microcracking (Figs. 1, 2 & 3). The inorganic filler particles were observed to separate out from the resin phase and congregate at the interface as the sealant flowed over the roughed lased surface.

At present, commercial RBFS are exclusively designed for acid-etched enamel. To take full advantage of the potential benefits of laser-conditioning, a new generation of fissure sealants is required that is specifically tailored to adhere and adapt to lased enamel.

**Conclusions:** Laser ablation may improve the retention of hydrophilic fissure sealants; although, further research is required to optimise lasing parameters and new RBFS are needed which are specifically designed to adhere and adapt to lased enamel.
